**Background:** Premature atrial contractions (PACs) are predictors of atrial fibrillation, stroke, and cardiovascular mortality. The present study aimed to assess relevant factors for PACs among a general population of Japanese men.

**Methods and Results:** This study conducted a population-based, cross-sectional study among 517 men, aged 40–79 years, with neither apparent myocardial infarction nor atrial fibrillation. 24-h Holter electrocardiography to assess PAC frequency was used. Age, body mass index, height, low-density lipoprotein cholesterol, triglycerides, high-density lipoprotein cholesterol, mean heart rate, diabetes mellitus, hypertension, physical activity, smoking, alcohol consumption, and lipid-lowering therapy were included in multivariable negative binomial regression analyses to assess correlation for the number of PACs per hour. Almost all participants (99%) had at least 1 PAC in 1 h (median number 2.84 PACs per h). In multivariable negative binomial regression after adjusting for all covariates simultaneously, age (relative risk [95% confidence interval], 1.30 [1.08–1.57] per 1-standard deviation [SD] increment), height (1.19 [1.02–1.39] per 1-SD increment), triglycerides (0.79 [0.65–0.97] per 1-SD increment), mean heart rate (0.69 [0.59–0.80] per 1-SD increment), physical activity (0.63 [0.43–0.93]), current smoking (1.69 [1.06–2.69]), current moderate (1.97 [1.23–3.16]) and heavy (1.84 [1.12–3.01]) alcohol consumption were independently associated with PAC frequency.

**Conclusions:** PAC frequency was independently associated with age, height, smoking, alcohol consumption, heart rate, physical activity, and triglycerides.

**Key Words:** Atrial fibrillation; Cardiovascular diseases; Epidemiology; Premature atrial contractions; Risk factors

Atrial fibrillation (AF), the most common type of cardiac arrhythmia, can cause substantial mortality, stroke, and heart failure, and is responsible for reduced quality of life.<sup>1,2</sup> Some cardiovascular risk factors, including elevated blood pressure, obesity, diabetes, and smoking, have been demonstrated as important determinants of AF.<sup>3,4</sup> Although guideline-adherent antithrombotic treatment is important,<sup>5</sup> there is also increasing interest in premature atrial contraction (PACs) as a crucial subclinical arrhythmia related to AF, stroke, and mortality.<sup>6–8</sup> However, studies that have assessed the prevalence of PACs and the association between PACs and cardiovascular risk factors in a general population are scarce.<sup>9</sup> Furthermore, the epidemiology of PACs and their determinants may be more important in East Asia, where the stroke is

dominant among cardiovascular diseases.<sup>10</sup>

Therefore, the present study aimed to assess the prevalence and relevant factors for PACs among a general population of Japanese men aged between 40 and 79 years.

## Methods

### Study Participants and Setting

The Shiga Epidemiological Study of Subclinical Atherosclerosis (SESSA) is a population-based observational study examining determinants of subclinical atherosclerosis. The design of this study and the information regarding baseline characteristics have been described previously.<sup>11</sup> In brief, from 2006 to 2008, the investigators from SESSA randomly selected and invited 2,379 Japanese men aged

between 40 and 79 years from Kusatsu City in Shiga prefecture, based on the Basic Residents' Register of the city. Among them, 1,094 men participated in the baseline assessment. During the follow-up examination from October 2010 to August 2014, 853 of the original participants were reassessed. For the current research, they were invited to join the SESSA Holter Study from October 2014 through September 2015, and a total of 542 agreed to participate (Figure 1). We excluded 10 with known myocardial infarction and 15 diagnosed with persistent or paroxysmal AF. The remaining 517 men were analyzed for the present study. Written informed consent was obtained from all participants prior to the study. The study followed the code of ethics of the World Medical Association (1975 Declaration of Helsinki). The study obtained approval from the Institutional Review Board of Shiga University of Medical Science (G2008-61).

### Holter Electrocardiography

Details of Holter electrocardiography have been described previously.<sup>12</sup> We used a 2-channel digital device (FM 800; Fukuda Denshi, Tokyo, Japan) with a frequency response of 0.05–40.0 Hz, sampling frequency of 125 Hz, and resolution of 10 bits for 24-h Holter recordings to assess PACs. All recordings were scanned and interpreted via SCM-510 software (Fukuda Denshi, Tokyo, Japan) and interpreted by using the interactive method. We have counted the short run of PACs and took those into account while counting PACs. The SCM-510 software was programmed to automatically identify arrhythmic events or artificial

noises. The basis of verification of PAC consisted of 3 criteria: prematurity, post-contraction pause, and morphology.<sup>6</sup> A PAC was defined by a coupling interval to the preceding QRS complex <70% of the mean RR interval, and the QRS complexes had a duration of <0.11 s unless aberration was suspected and the post-contraction pause had to be non-compensatory. The total number of PACs was summed during the entire period. To account for the slight variations in recording time, the mean number of PACs per h was used as the primary outcome variable in this study. The primary editing and analyses were manually performed by one well-trained medical technologist supervised by one expert cardiologist (T.H.), certified by the Japanese Circulation Society, who were blinded regarding the status and related information of participants. Regarding ensuring intrareader reproducibility of PAC, it was tested by a blinded reanalysis of a random sample of 50 recordings, and the intraclass correlation coefficient was 0.97. The median (25%, 75% tiles) of the recording duration was 24.0 (23.6, 24.4) h, and all recordings met the definition of a valid recording as a recording duration of at least 18 h.<sup>9</sup>

We also assessed premature ventricular contractions (PVCs); frequency response of 0.05–40.0 Hz, sampling frequency of 125 Hz, and resolution of 10 bits for 24-h Holter recordings. PVCs were defined as premature beats with a QRS duration of >120 ms and different QRS-wave and T-wave morphology compared with normal sinus beats. The intrareader reproducibility of PVCs was also tested by a blinded reanalysis of a random sample of 50 recordings,

<b>Table 1. Participant Characteristics Stratified by the Median Number of PACs per h, SESSA, Shiga, Japan (2010–2015)</b>

Heavy	44 (17.0)	36 (13.95)	

Data are expressed as median (interquartile range) or n (%). Number of observations across the categories may not add up to the total given number because of missing data. Diabetes mellitus was defined as fasting glucose of  $\geq 126$  mg/dL, hemoglobin A1c of  $\geq 6.5\%$ , or the use of any antidiabetic medication. Hypertension was defined as systolic BP of  $\geq 140$  mmHg, diastolic BP of  $\geq 90$  mmHg, or use of antihypertensive medication. The participants who exercised more than 10 min regularly over the current 3 months or more were defined as physically active. \*Based on the unpaired Student's t-test/Wilcoxon rank-sum test for continuous variables and a chi-squared test for categorical variables. BMI, body mass index; BP, blood pressure; eGFR, estimated glomerular filtration rate; HbA1c, hemoglobin A1c; HDL-C, high-density lipoprotein cholesterol; HR, heart rate; LDL-C, low-density lipoprotein cholesterol; PAC, premature atrial contraction; PVC, premature ventricular contraction; SESSA, Shiga Epidemiological Study of Subclinical Atherosclerosis.

and the intraclass correlation coefficient was 0.99. The median (25%, 75% tiles) of the recording duration was 24.0 (23.6, 24.4) h. All recordings met the definition of a valid recording with a recording duration of at least 18 h.<sup>9</sup>

### Study Variables

Demographic data, medical history, use of medications, and lifestyle factors including smoking and alcohol consumption were collected from the participants by trained research technicians using a self-administered questionnaire. Details of the assessment of covariates have been described elsewhere.<sup>11</sup> Briefly, smokers and alcohol drinking habits were defined as either “current” (smoke/consume alcohol in the last 30 days), “past” (those who quit 30 days prior to the study), or “never” (those who never smoke/consume alcohol). “Current drinkers” were again subdivided into

“light drinkers” (<23 g/day), “moderate drinkers” (>23–46 g/day), or “heavy drinkers” (>46 g/day). We asked drinkers to estimate the frequency and amount of alcohol they consume during a usual week. Volumes were converted to the estimated amount of ethanol consumed in grams per week.<sup>13</sup>

Body mass index (BMI) was defined as body weight (kg) divided by the square of the height (m). Using an automated sphygmomanometer (BP-8800SF; Omron Health Care, Kyoto, Japan), the mean of 2 consecutive measurements on the right arm with participants in a seated position after a strict 5-min rest period was used to determine blood pressure. Hypertension was defined as systolic blood pressure of  $\geq 140$  mmHg, diastolic blood pressure of  $\geq 90$  mmHg, or use of antihypertensive medication. Heart rate was measured as heartbeats per minute on a 24-h Holter electrocar-

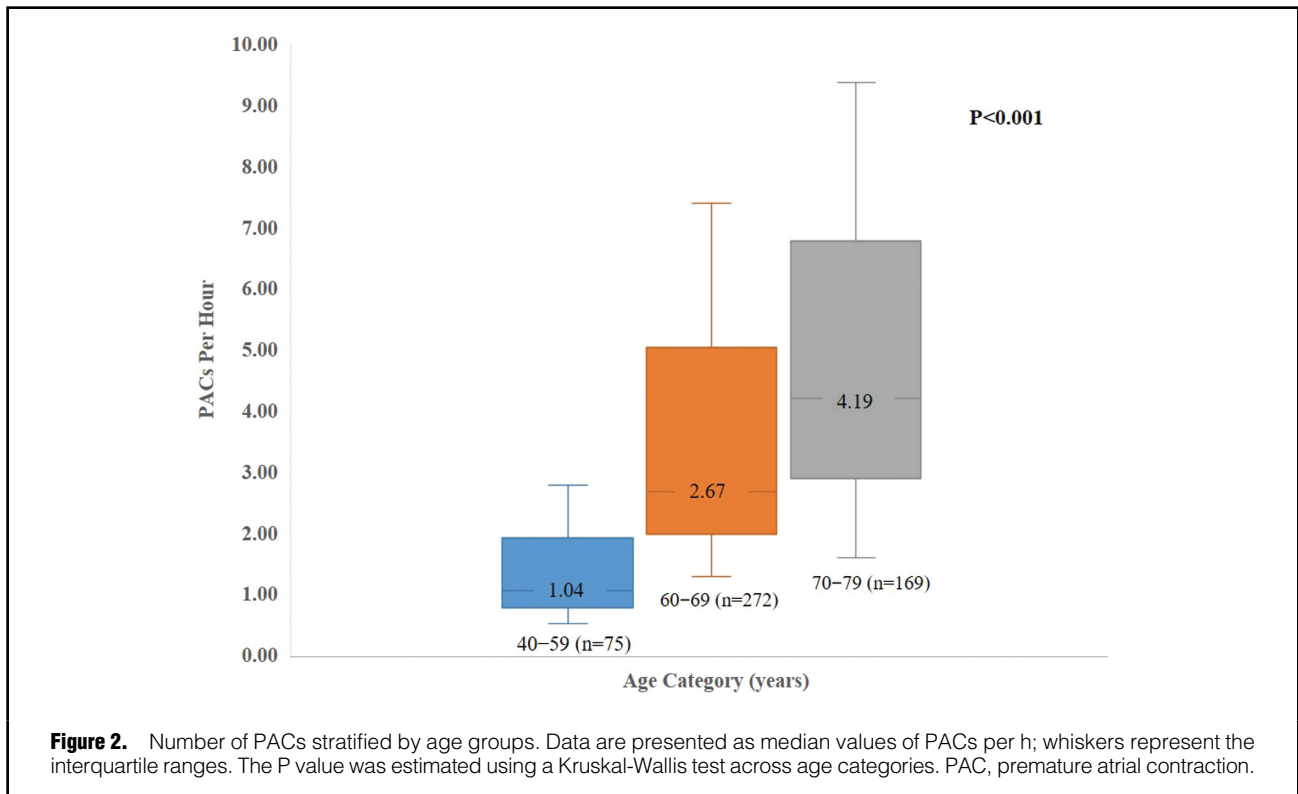

diagram. We used maximum (the highest value), resting (the lowest values usually in a resting position), and mean heart rate (the average value) recorded during 24 h. The participants who exercised more than 10 min over the current 3 months or more were defined as physically active, and the data were recorded as number of days per week of leisure-time physical activity.<sup>13</sup>

Venipuncture was performed early in the clinic visit following measurement of blood pressure after at least a 12-h fast. Samples were sent for routine laboratory tests including the assessment of lipid profiles and glucose. Total cholesterol and triglycerides were measured using enzymatic assays, and high-density lipoprotein (HDL) cholesterol was measured using a direct method (Kyowa Medix, Tokyo, Japan). We calculated low-density lipoprotein (LDL) cholesterol by using the Friedewald equation.<sup>14</sup> Lipid measurements were standardized annually according to the protocol of the Centers for Disease Control and Prevention/Cholesterol Reference Method Laboratory Network. Plasma glucose levels were determined by sodium fluoride-treated plasma using the hexokinase glucose-6 phosphate-dehydrogenase enzymatic assay. Glycated hemoglobin (HbA1c) was measured by the latex agglutination inhibition assay according to either the Japan Diabetes Society (JDS) protocol or that of the National Glycohemoglobin Standardization Program (NGSP). JDS values were converted to NGSP values using the equation recommended by the JDS as follows: NGSP value (%) =  $1.02 \times \text{JDS value} (\%) + 0.25$ .<sup>15</sup> Diabetes mellitus was defined as fasting glucose of  $\geq 126$  mg/dL or HbA1c (NGSP) of  $\geq 6.5\%$ , or use of any antidiabetic medication. Serum creatinine levels were measured using an enzymatic assay (Espa CRE-liquid II; NIPRO, Osaka, Japan). The estimated glomerular filtration rate (eGFR) was calculated using serum creatinine levels

for Japanese men:  $\text{eGFR (mL/min/1.73 m}^2\text{)} = 194 \times \text{serum creatinine}^{-1.094} \times \text{age}^{-0.287}$ .<sup>16</sup>

### Statistical Analysis

The participants were divided into 2 groups based on the median value of PACs per h (2.85 PACs per h). Participants' characteristics are shown using medians and interquartile ranges for continuous variables and percentages for categorical variables. The characteristics between the 2 groups were compared using the unpaired Student's t-test or Wilcoxon rank-sum test for continuous variables and the chi-squared test for categorical variables. Number of PACs per h according to age categories (40-59, 60-69, and 70-79 years) was compared by using the Kruskal-Wallis test. Similarly, the number of PACs were also compared according to height, mean heart rate, triglycerides, physical activity, smoking, and drinking categories. We performed a negative binomial regression to assess the factors independently related to the number of PACs per h.<sup>9</sup> Our analyses were performed with sequential adjustment: Model 1 was adjusted for age and Model 2 was simultaneously adjusted for all variables. To assess whether number of PVCs was associated with PAC frequency, we additionally added number of PVCs to a multivariable model. Covariates with a skewed distribution were log transformed; missing data were not included in the analyses.

For selection of the appropriate variables for statistical modeling, we performed the stepwise approach based on the value of the Akaike Information Criterion, which gives a measure of the goodness of fit. We also checked background information carefully to identify the clinically strong variables to set our final analysis model. Because aging itself is related to other cardiovascular risk factors, we also checked for the interaction of age with related fac-

**Table 2. Negative Binomial Regression to Assess Variables Related to the Number of PACs per h**

Variables	Model 1		Model 2	
	Risk ratio* (95% CI)	P value	Risk ratio* (95% CI)	P value
Age (per 1-SD)	1.37 (1.20–1.58)	<0.001	1.30 (1.08–1.57)	<0.001

No. of PVCs per h	1.28 (0.81–2.02)	0.287	1.07 (0.61–1.87)	0.799

Model 1 is adjusted for age; Model 2 includes all variables simultaneously. \*Data are risk ratio per 1-SD increment for continuous variables or compared with the reference group for categorical variables. Age (per 1-SD)=7.24 years; BMI (per 1-SD)=2.80 kg/m<sup>2</sup>; Height (per 1-SD)=0.05 m; LDL-C (per 1-SD)=30.5 mg/dL; Triglycerides (log per 1-SD)=0.53; HDL-C (per 1-SD)=17.0 mg/dL; Mean HR (per 1-SD)=7.0 beats/min; No. of PVCs (per 1-SD)=2 counts/h. CI, confidence interval; HR, heart rate; SD, standard deviation. Other abbreviations as in Table 1.

tors showing no persistent interaction between them (non-significant). For the sensitivity analysis, we examined the quartiles of number of PACs per h ( $\leq 1.19$ , 1.20–2.84, 2.85–7.86, and  $>7.86$ ) as dependent variables in multivariable ordinal logistic regression. We also performed a negative binomial regression analysis excluding the participants with anti-hypertensive medication use because  $\beta$ -blockers or calcium channel blockers may affect the incidence of PACs. Furthermore, we estimated the risk ratios (RRs) and 95% confidence intervals (CIs) per 10-unit increment in age [years], HDL-C [mg/dL], LDL-C [mg/dL], and mean heart rate [beats/min]; per 1-unit increment in BMI [kg/m<sup>2</sup>] and TG [log]; per 0.1 unit increment in height [m] for PAC frequency. All analyses were performed by using SAS version 9.4 (SAS Institute, Cary, NC, USA). A 2-tailed P value of  $<0.05$  was prespecified to indicate statistical significance.

## Results

The mean age of the participants was 66.6 (standard deviation [SD], 7.2) years. PACs were very common, as 99% (n=513) of the participants had at least 1 PAC on 24-h Holter electrocardiogram. **Table 1** shows the characteristics of participants stratified by the median number of PACs per h. The group having a higher number of PACs was older and had lower levels of resting and mean heart rates, and lower triglycerides, compared with the group with a lower number of PACs.

In **Figure 2**, the median number (interquartile range) of PACs per h was 1.04 (0.50–2.78), 2.67 (1.28–7.39), and 4.19 (1.58–9.37) among the participants aged 40–59, 60–69, and 70–79 years, respectively ( $P<0.001$ ). In **Supplementary**

**Figure A–F**, the median number (interquartile range) of PACs per h according to categories of height, was 3.28 (1.39–7.72), 2.05 (1.01–7.87), 2.94 (1.30–7.75), triglycerides was 3.28 (1.55–9.47), 3.41 (1.38–9.65), 2.14 (0.87–5.22), mean heart rates were 3.92 (1.53–9.74), 2.74 (1.18–6.91), 2.05 (1.00–6.80); physical activity categories was 3.42 (1.19–8.48), 2.66 (1.05–6.65); smoking and drinking categories was 2.89 (1.28–6.48), 2.75 (1.19–7.52), 3.37 (1.03–10.47) and 3.23 (1.04–7.27), 3.94 (1.67–12.54), 2.78 (1.19–7.83) respectively.

The results from a negative binomial regression are shown in **Table 2**. In Model 1, adjustment for age showed that height (RR per 1-SD increment, 1.22; 95% CI, 1.06–1.40;  $P<0.001$ ), HDL cholesterol (RR per 1-SD increment, 1.30; 95% CI, 1.10–1.54;  $P<0.001$ ), and current moderate alcohol consumption compared with never consumers (RR, 1.64; 95% CI, 1.06–2.54;  $P<0.05$ ) were positively associated with the number of PACs per h, whereas LDL cholesterol (RR per 1-SD increment, 0.86; 95% CI, 0.75–0.98;  $P<0.05$ ), triglycerides (RR per 1-SD increment, 0.81; 95% CI, 0.67–0.97;  $P<0.05$ ), mean heart rate (RR per 1-SD increment, 0.76; 95% CI, 0.64–0.89;  $P<0.001$ ), and physical activity (RR, 0.60; 95% CI, 0.42–0.85;  $P<0.01$ ) were inversely associated with the number of PACs per h. After adjustment by all covariates simultaneously (Model 2), age (RR per 1-SD increment, 1.30; 95% CI, 1.08–1.57;  $P<0.001$ ), height (RR per 1-SD increment, 1.19; 95% CI, 1.02–1.39;  $P<0.05$ ), current smoking (RR, 1.69; 95% CI, 1.06–2.69;  $P<0.05$ ), and current moderate (RR, 1.97; 95% CI, 1.23–3.16;  $P<0.01$ ) and heavy (RR, 1.84; 95% CI, 1.12–3.01;  $P<0.05$ ) alcohol consumption were positively associated with the number of PACs per h, whereas triglycerides (RR per 1-SD increment, 0.79; 95% CI, 0.65–0.97;  $P<0.05$ ),

No. of PVCs per h	1.39 (0.73–2.66)	0.306	1.29 (0.59–2.81)	0.511

Model 1 is adjusted for age; Model 2 includes all variables simultaneously. \*Data are odds ratio per 1-SD increment for continuous variables and compared with reference group for categorical variables. Age (per 1-SD)=7.24 years; BMI (per 1-SD)=2.80 kg/m<sup>2</sup>; Height (per 1-SD)=0.05 m; LDL-C (per 1-SD)=30.5 mg/dL; Triglycerides (log per 1-SD)=0.53; HDL-C (per 1-SD)=17.0 mg/dL; Mean HR (per 1-SD)=7.0 beats/min; No. of PVCs (per 1-SD)=2 counts/h. Abbreviations as in Tables 1,2.

mean heart rate (RR per 1-SD increment, 0.69; 95% CI, 0.59–0.80;  $P<0.001$ ), and physical activity (RR, 0.63; 95% CI, 0.43–0.93;  $P<0.005$ ) were inversely associated with the number of PACs per h. BMI as a continuous variable showed a borderline association with number of PACs per h (RR per 1-SD increment, 1.18; 95% CI, 0.99–1.41;  $P=0.051$ ). Additionally, we defined obesity based on a BMI  $\geq 25$  kg/m<sup>2</sup> as a categorical variable, and we found a strong association between obesity and PAC frequency in both Model 1 (RR, 1.73; 95% CI, 1.25–2.40;  $P<0.001$ ) and Model 2 (RR, 2.34; 95% CI, 1.63–3.37;  $P<0.001$ ) (data not shown in tables to avoid concern of over adjustments).

In multivariable ordinal logistic regression (Table 3), age (odds ratio [OR] per 1-SD increment, 1.94; 95% CI, 1.59–2.37;  $P<0.001$ ), height (OR per 1-SD increment, 1.30; 95% CI, 1.08–1.56;  $P<0.05$ ), triglycerides (OR per 1-SD increment, 0.76; 95% CI, 0.62–0.93;  $P<0.05$ ), and mean heart rate (OR per 1-SD increment, 0.73; 95% CI, 0.62–0.86;  $P<0.001$ ) showed independent associations with PAC frequency (Model 2).

In negative binomial regression analysis (Supplementary Table 1), after excluding those participants having a history of anti-hypertensive medication ( $n=328$ ) use, age (RR per 1-SD increment, 1.25; 95% CI, 1.08–1.57;  $P<0.001$ ), triglycerides (RR 0.79; 95% CI, 0.65–0.97;  $P<0.050$ ), mean heart rate (RR 0.78; 95% CI, 0.65–0.94;  $P<0.050$ ), physical activity (RR, 0.71; 95% CI, 0.43–0.93;  $P<0.050$ ), current smoking (RR, 1.62; 95% CI, 1.02–2.95;  $P<0.05$ ), and current light (RR, 2.63; 95% CI, 1.02–6.77;  $P<0.05$ ) and heavy drinking (RR, 2.59; 95% CI, 1.37–4.89;  $P<0.010$ ) showed an independent association with PACs (Model 2). In Supplementary Table 2, we observed similar results; age (RR, 1.45; 95% CI [1.12–1.87] per 10-years increment),

height (1.02 [1.01–1.05] per 0.1 meter increment), triglycerides (0.69 [0.49–0.97], log, per 1-unit increment), mean heart rate (0.65 [0.54–0.78] per 10 beats/min increment), physical activity (0.63 [0.43–0.93]), current smoking (1.69 [1.06–2.69]), current moderate (1.97 [1.23–3.16]) and heavy (1.84 [1.12–3.01]) alcohol consumption were associated with PAC frequency.

## Discussion

In this population-based study of apparently healthy middle-aged to older men, the number of PACs per h was associated with age, height, smoking, alcohol consumption, heart rate, physical activity, and triglycerides. To our best knowledge, this is the first population-based study in East Asia to examine the burden of PACs based on 24-h Holter monitoring data and their determinants, where stroke is dominant among cardiovascular diseases. Our findings are also comparable with those reported in Western countries with similar interests.<sup>9,17</sup>

In our study, we estimated that 99% of all participants had at least 1 PAC during 24h. The distribution of a higher number of PACs was higher among older participants. Similarly, a higher number of PACs was observed with advancing age among middle-aged or older participants from the Cardiovascular Health Study (age range, >65 years)<sup>17</sup> and from the Swiss cohort Study on Air Pollution and Lung Diseases in Adults (SAPALDIA) (age range,  $\geq 50$  years).<sup>9</sup>

Our study has revealed the interesting finding of an inverse association between PAC frequencies and mean heart rates; a previous study focusing on AF also reported similar findings.<sup>18</sup> Lower heart rate could be related to larger

stroke volume, possibly leading to increased atrial stretch or strain, which might result in structural and electrical remodeling and can initiate AF.<sup>19</sup> Furthermore, lower heart rate is also known as a measure of autonomic imbalance leading to AF.<sup>20</sup> Understandably a large number of PACs are associated with higher risk of AF occurrence;<sup>6</sup> another explanation could simply be that when the heart rate is lower, there is more time for an extra beat to occur; finally, we may assume that the association between PAC frequency and lower heart rate follows pathophysiology similar to that for AF.<sup>19</sup>

We also first revealed an interesting inverse association between PAC frequency and triglyceride levels. It has been reported by recent studies showing that lipid profiles, including triglycerides, have an inverse association with AF.<sup>21,22</sup> The pathophysiology behind this inverse association may be explained by the fact that as all cholesterol including triglycerides are essential for the cell membrane, changes in cholesterol levels can lead to alteration of cell membrane properties that can affect cell membrane permeability and membrane proteins including ion channels, pumps, and receptors,<sup>23</sup> which can hamper electrical gradient and resting potential through the cell membrane, leading to vulnerability to arrhythmia. In the SAPALDIA study,<sup>9</sup> they reported an inverse association between HDL-C and PACs frequency because the overall inverse relationship between HDL cholesterol and cardiovascular disease, including incident AF, might be the pathophysiology.<sup>24,25</sup> Controversially, this finding could not be confirmed in a more recent analysis as no significant association between HDL-C and incident AF was found.<sup>26</sup> In terms of LDL-C, being an essential lipid for the cell membrane and was found to be inversely related to incident AF,<sup>26</sup> we could not report any association with PACs, similar to findings of a prior study.<sup>9</sup> The difference in the findings between the SAPALDIA study and ours may be due to the differences in participants' characteristics (e.g., race/ethnicity, age, or sex) or discrepancies in lipid levels; however, for further evaluation, future studies are required.<sup>27</sup>

BMI, as a continuous variable, showed a borderline positive association with PAC frequency, whereas defined obesity (BMI  $\geq 25$  kg/m<sup>2</sup>) as a categorical variable showed a significant association with PAC frequency. Obesity adversely affects cardiovascular hemodynamics and cardiac structures, and increases risk of incident AF through the development of the electro-anatomic remodeling in the atrium.<sup>3,28,29</sup> However, cross-sectional analyses from the SAPALDIA study did not report such an association between BMI and PACs,<sup>9</sup> perhaps because of the difference in the distribution of BMI between the cohorts, or the Japanese population being thinner.

Previous studies<sup>9,30-34</sup> have revealed an association between AF and height, smoking, and drinking habits; we also reported positive associations of height, current smoking, and drinking habits with a larger number of PACs. It has been hypothesized that the higher frequency of PACs among taller individuals may be a result of a close relationship between body size and left atrial size.<sup>33</sup> Interestingly, genetic or early-life determinants might play an important role in this relationship.<sup>30</sup> An earlier study has revealed a positive association between PACs and being taller among the Western population;<sup>9</sup> we have found similar findings in an Asian population. To confirm the effect of any ethnic variation on PACs, future studies are recommended. Smoking contributes to the development of atrial fibrosis

via nicotine, which can lead to atrial arrhythmias by reducing electrical impulse conduction in cardiac tissue.<sup>35</sup> A systematic review and meta-analysis clarified that the risk for current smokers of developing AF was higher than that in former smokers.<sup>36</sup> Our study reported that current smoking, but not former smoking, was positively associated with PAC frequency, suggesting that a longer time since quitting smoking might be associated with a lower likelihood of atrial arrhythmia.

Higher alcohol consumption was linked to a higher risk of AF,<sup>32</sup> which may result from an alcoholic heart disorder such as cardiomyopathy;<sup>31</sup> however, data from previous epidemiological studies showed that mild-to-moderate alcohol consumption protected against the development of heart failure,<sup>37</sup> which could lead to a lower risk of atrial arrhythmia. Therefore, our finding regarding the association between moderate alcohol consumption and PAC frequency remains controversial.

We found an inverse association between physical activity and number of PACs per h. Our findings support the previous findings of the SAPALDIA study.<sup>9</sup> A prospective cohort study reported that moderate physical activity was associated with a reduced risk of AF, whereas higher activity attenuated the benefits of moderate activity on AF risk, suggesting a J-shaped relationship between leisure-time physical activity and AF,<sup>38</sup> indicating that vigorous activity might increase the risk of AF. In our current research, we did not collect information regarding physical activity levels; therefore, it is difficult to explain the underlying pathophysiology clearly.

Regarding the sensitivity analysis, we chose to perform ordinal logistic regression to discover how the dependent variable behaves (quartiles of PACs per h) in an ordinal fashion to each independent variable. The different outcomes in ordinal logistic regression may cause some determinants to be missed in comparison with negative binomial regression (Table 2). For Supplementary Table 1, a negative binomial regression analysis was performed, excluding participants with anti-hypertensive medication use, because  $\beta$ -blockers or calcium channel blockers may affect the incidence of PACs and observed results of this study.

### Study Limitations

Several limitations of the present study warrant consideration. First, we studied only middle-aged to older men, and the sample was obtained from a single area in Japan, both of which may limit the generalizability of the present study results. Second, owing to the cross-sectional study design, the true relationship between PACs and their determinants might have been somewhat diluted. Third, the number of PACs recorded may have had day-to-day variability, which we were unable to assess because only 1 recording per individual was obtained. Assuming that this variability is random, this might have slightly reduced our power to detect significant associations. Fourth, we currently do not have the data for  $\beta$ -blocker and other antiarrhythmic drug intake for the present study. Fifth, in the current study, we could not indicate the relationship of heart rate per each clock hour (circadian variation) or biomarkers representing myocardial damage (e.g., B-type natriuretic peptide, troponin, or creatine phosphokinase) and PAC frequency. Finally, as very few earlier studies have been conducted primarily focusing on the risk factors for PACs, in some cases, we had to discuss possible pathophysiologies regarding

AF that are not directly related to PACs; therefore, evidence for this particular field is essential.

## Conclusions

In a middle-aged to older male cohort of the general population in Japan with neither apparent cardiovascular disease nor AF, the majority of the participants had at least 1 PAC per h on a 24-h Holter electrocardiogram. Age, height, current smoking, current alcohol consumption, heart rate, physical activity, and triglycerides were identified as independent determinants of PAC frequency. This study has generated new knowledge about the modifiable determinants for the prevention of PACs related to future AF and stroke, and expressly underlines the importance of a healthy lifestyle. Future research is warranted to investigate the association of frequent PAC with incident AF among this study population.

## Acknowledgments

The authors thank the SESSA investigators, staff, and study participants for their dedication and commitment. The names of the members of the SESSA research group have been provided in the **Supplementary File**. We also thank Ms. Muramatsu for providing assistance with the analysis of Holter electrocardiograms.

## Sources of Funding

This study has been funded by Grants-in-Aid for Scientific Research: (A) 13307016, (A) 17209023, (A) 21249043, (A) 23249036, (A) 25253046, (A) 15H02528, (A) 18H04074, (C) 20K10529, Grants-in-Aid for Scientific Research Young Scientists: (B) 17K15827; Research Activity Start-up 25893097 from the Ministry of Education, Culture, Sports, Science, and Technology, Japan; by grant R01HL 068200 from the National Institute of Health, Japan; and from Kao Research Council for the Study of Healthcare Science (Tokyo, Japan).

## Disclosures

The authors declare no conflicts of interest.

## IRB Information

This study was approved by the Institutional Review Board of Shiga University of Medical Science (G2008-61).

## Data Availability

The deidentified participant data will not be shared.
